Cosmology and stellar physics with strongly lensed supernovae from Rubin-LSST

Supernovae (SNe) that are gravitationally lensed into multiple images offer interesting avenues to probe stellar physics and cosmology. Firstly, the time delays between the multiple images of a lensed SN allow to measure the Hubble constant (H0) independently from other probes, in order to assess the current tension on H0 and the possible need for new physics. Secondly, these time delays also help constrain the SN progenitor scenarios by facilitating follow-up observations in the first hours after explosion. In this talk, I will show the advantages of measuring H0 with lensed SNe compared to lensed quasars, and I will present forecasts on the precision achievable with lensed SN samples drawn from Rubin-LSST. I will then describe our deep learning methods to search for lensed SNe in current and future wide-field time-domain surveys. I will finally introduce our recent efforts to mitigate for the impact of microlensing and to develop new strong lens modeling techniques with deep learning.
